

Energy dissipation rate limits for flow through rough channels and tidal flow across topography

R. R. Kerswell

(Received 4 August 2016)

An upper bound on the energy dissipation rate per unit mass, ε , for pressure-driven flow through a channel with rough walls is derived for the first time. For large Reynolds numbers, Re , the bound - $\varepsilon \leq cU^3/h$ where U is the mean flow through the channel, h the channel height and c a numerical prefactor - is independent of Re (i.e. the viscosity) as in the smooth channel case but the numerical prefactor c , which is only a function of the surface heights and surface gradients (i.e. not higher derivatives), is increased. Crucially, this new bound captures the correct scaling law of what is observed in rough pipes and demonstrates that while a smooth pipe is a singular limit of the Navier-Stokes equations (data suggests $\varepsilon \sim 1/(\log Re)^2 U^3/h$ as $Re \rightarrow \infty$), it is a regular limit for current bounding techniques. As an application, the bound is extended to oscillatory flow to estimate the energy dissipation rate for tidal flow across bottom topography in the oceans.

1. Introduction

In every turbulent flow, there is some key quantity of interest which is either enhanced or suppressed compared to its laminar value and it is of fundamental interest to understand this effect as a function of the parameters of the problem. Well known examples include the mass flux along a channel driven by an applied pressure gradient, the heat flux across a differentially heated fluid layer or the wall shear stress exerted by a fluid sheared between two parallel plates. One approach is to derive strict inequality information on these key global flow quantities as a function of the system parameters in the hope that this captures the correct scaling relationship. This ‘bounding’ approach is attractive because it seeks to extract just enough of the physics from the governing equations to make the correct prediction while eschewing other secondary flow details which arise from directly solving the governing equations and just may not be attainable in the asymptotic regime of interest (e.g. vanishing viscosity). The downside of the bounding approach is that the bound derived can be too conservative. Well known examples are the energy dissipation rate ε in a smooth pipe where the best (lowest) bound known predicts that ε approaches a finite constant (in units of U^3/h) as the Reynolds number Re becomes large - so called Kolmogorov scaling (Frisch 1995) - whereas data suggests $\sim 1/(\log Re)^2$ drop off, and the scaling of the Nusselt number Nu (normalised heat flux) in Boussinesq convection with Rayleigh number Ra : the bound has $Nu \lesssim Ra^\alpha$ with $\alpha = \frac{1}{2}$ for $Ra \rightarrow \infty$ whereas current data suggests more $\alpha \approx 0.31$ (e.g. see the discussion in Waleffe et al. (2015)) with probable dependence on the Prandtl number too (Grossmann & Lohse 2000).

The bounding approach owes its roots to a suggestion by Malkus (1954) that turbulent flows want to maximise their transport and was first applied in convection by Howard (1963) and in shear flows by Busse (1969,1970) (see Howard 1972 and Busse 1978 for early reviews). The original approach was based on using certain simple projections of the governing equations as constraints in an optimisation problem. After initial successes, it quickly became hard to pose more constrained yet still tractable problems and the field languished in the late 70s and 80s. In the early 90s, a new ‘background’ method introduced by Constantin and Doering (Doering & Constantin 1992, 1994, 1996; Constantin & Doering 1995) revitalised the field by providing an alternative way to systematically derive rigorous bounding results (Marchioro 1994; Kerswell 1996, 2002; Wang 1997; Nicodemus et al. 1997; Hoffmann & Vitanov 1999; Doering and Constantin 2001; Doering and Foias 2002; Otero et al. 2002; Plasting & Kerswell 2003, 2005; Plasting & Ierley 2005; Wittenberg 2010; Whitehead & Doering 2011; Whitehead & Wittenberg 2014; Wen et al. 2013). The key idea (traceable back to Hopf) is to decompose the flow variables into a steady incompressible ‘background’ field which carries the inhomogeneities of the problem and a fluctuating incompressible part which is unforced and hence of arbitrary amplitude. The method then proceeds by designing the background field (typically with a boundary layer of thickness δ) so that the influence of the unknown fluctuating field on the key functional of interest can be bounded (by taking δ small enough). While very successful (e.g. see Wang (1997) for a proof of an upper bound on ε for a general domain where the boundary moves tangentially to itself everywhere), the method does have its limitations most notably illustrated by the problem of pressure-driven flow across a rough wall. Here the background flow must bring an $O(1)$ (relative to $\delta \rightarrow 0$) normal component of the exterior flow to zero at the rough wall surface over a boundary layer distance of $O(\delta)$. Incompressibility then forces the background flow to have an $O(1/\delta)$ component locally tangent to the rough wall and control of the unknown fluctuating part is lost (technically the required spectral constraint cannot be satisfied). Incompressibility of the background field is the key obstacle here: relaxing the constraint on the background field causes problems elsewhere (the fluid pressure can’t be eliminated from the analysis) or when it is not relevant - in the case of convection where only a background temperature field is needed - there is no problem (Goluskin & Doering 2016).

In the last 5 years, a *second* new bounding method has been developed by Otto and Seis (Otto & Seis 2011; Seis 2015) - hereafter referred to as the ‘boundary layer’ method - which potentially offers a new line of attack on the roughness problem. In this paper we discuss how this method can indeed be extended to deliver a first rigorous upper bound on the energy dissipation rate for pressure-driven flow through a rough channel. Interestingly, the same scaling law emerges for the bound on ε in terms of the applied pressure gradient as for the smooth channel situation (albeit with an enlarged numerical prefactor dependent on the exact form of the roughness). This is exactly what has also been found very recently for rough wall convection (using the background technique) in Goluskin & Doering (2016). Assuming the bound carries over to rough pipe flow, this then *matches* the observed scaling law for turbulent data (Moody 1944). There are two immediate implications: 1) a smooth wall is a singular limit of rough wall flows at high Re flows yet a *regular* limit for current upper bounding techniques; and 2) current upper bounding techniques are actually better at capturing scaling laws than has been immediately apparent by focussing on the singular case of smooth wall problems (see Goluskin & Doering (2016) for references which suggest that their rough wall bound may be consistent with convection data). To illustrate how the new energy dissipation rate bound can be utilized, we extend the result to oscillatory free-surface flow over one

FIGURE 1. The flow geometry. The top boundary is given by $z = g(x, y)$ and the bottom by $z = f(x, y)$. The intermediate surface shown in outline is parametrised by λ and defined by $z = F(x, y, \lambda) := (1 - \lambda)f(x, y) + \lambda g(x, y)$.

rough boundary which is a simple model of tidal flow over topography. Understanding how topography such as isolated ridges enhance dissipation and especially mixing processes is an important yet poorly-understood ingredient for ocean circulation modelling (e.g. see Melet et al. 2016 and references therein).

2. 3D Rough channel flow

Imagine a channel of average height h , periodic extent hL_x in the (streamwise) direction of an applied pressure gradient and periodic spanwise extent hL_y . If ν is the kinematic viscosity, then introduce ν/h as the unit of speed, h as the unit of length and h^2/ν as the unit of time. The governing Navier-Stokes equations become

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} + \nabla p - \nabla^2 \mathbf{u} = Gr \hat{\mathbf{x}}, \quad (2.1)$$

$$\nabla \cdot \mathbf{u} = 0, \quad (2.2)$$

where $Gr := h^3 \mathcal{G} / \nu^2$, the Grashof number, is the non-dimensionalised applied pressure gradient \mathcal{G} driving the flow. For convenience we refer to the cross channel z -direction as the ‘vertical’ direction and the x and y directions as horizontal and imagine rough channel boundaries at $z = f(x, y)$ (the lower boundary) and $z = g(x, y)$ (the upper boundary).

The roughness functions f and g will be assumed C^∞ , periodic over $\mathcal{A} := [0, L_x] \times [0, L_y]$ such that

$$\iint_{\mathcal{A}} f \, dx dy = 0 \quad \& \quad \frac{1}{A} \iint_{\mathcal{A}} g \, dx dy = 1 \quad (2.3)$$

(to preserve the average channel height as 1 in non-dimensional units and non-dimensional volume as $A := L_x L_y$) and to be such that the channel is never blocked at any point (i.e. $f < g$ for any $(x, y) \in \mathcal{A}$). In the following we work with a 1-D family of interior surfaces

$$\mathcal{S}(\lambda) := \{(x, y, z) \mid z = F(x, y, \lambda) := (1 - \lambda)f(x, y) + \lambda g(x, y) \text{ for } (x, y) \in \mathcal{A}\} \quad (2.4)$$

with $\lambda \in [0, 1]$ which smoothly interpolate between the two rough boundaries: $\lambda = 0$ giving the lower boundary and $\lambda = 1$ the upper boundary: see figure 1. Let $\mathcal{C}(\lambda, y^*)$ be the line formed from the intersection of $\mathcal{S}(\lambda)$ with the $y = y^*$ plane. Let $\mathcal{V}(\lambda)$ be the volume enclosed by $\mathcal{S}(\lambda)$, $\mathcal{S}(0)$ (the lower boundary) and the planes $x = 0$, $x = L_x$, $y = 0$ and $y = L_y$, and let $\partial\mathcal{V}(\lambda)$ be the boundary of \mathcal{V} . The flow conditions at the edges of each surface are periodic so that the flow is invariant under the transformations $x \rightarrow x + L_x$ and $y \rightarrow y + L_y$. A long time average is defined as

$$\langle (\cdot) \rangle := \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T (\cdot) \, dt. \quad (2.5)$$

We start the ‘boundary layer’ bounding analysis (Otto & Seis 2011; Seis 2015) by taking the line integral of (2.1) along $\mathcal{C}(\lambda, y)$ (in the direction of increasing x) followed by an integration over y ,

$$\int_0^{L_y} \int_{\mathcal{C}(\lambda, y)} \hat{\mathbf{s}} \cdot \left[\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} + \nabla p - \nabla^2 \mathbf{u} \right] ds \, dy = Gr \int_0^{L_y} \int_{\mathcal{C}(\lambda, y)} \hat{\mathbf{s}} \cdot \hat{\mathbf{x}} \, ds \, dy \quad (2.6)$$

where s is the arc-length along $\mathcal{C}(\lambda, y)$ and $\hat{\mathbf{s}} := (\hat{\mathbf{x}} + F_x \hat{\mathbf{z}}) / \sqrt{1 + F_x^2}$ is the unit tangent vector (subscripts indicate partial derivatives so that $F_x = \partial F / \partial x$ with y and λ held fixed). Crucially, this procedure kills the pressure term as

$$\int_{\mathcal{C}(\lambda, y)} \hat{\mathbf{s}} \cdot \nabla p \, ds = p(L_x, y, F(L_x, y, \lambda), t) - p(0, y, F(0, y, \lambda), t) = 0 \quad (2.7)$$

by periodicity in x . With this, and converting the line integral to an integration over x , we get

$$A Gr = \frac{\partial}{\partial t} \iint_{\mathcal{A}} (\hat{\mathbf{x}} + F_x \hat{\mathbf{z}}) \cdot \mathbf{u} \, dx \, dy + \iint_{\mathcal{A}} (\hat{\mathbf{x}} + F_x \hat{\mathbf{z}}) \cdot [\mathbf{u} \cdot \nabla \mathbf{u} - \nabla^2 \mathbf{u}] \, dx \, dy \quad (2.8)$$

The first term on the rhs can be dropped after long-time averages, assuming that the kinetic energy remains bounded in time, to leave

$$Gr = \left\langle \frac{1}{A} \iint_{\mathcal{A}} (\hat{\mathbf{x}} + F_x \hat{\mathbf{z}}) \cdot [\mathbf{u} \cdot \nabla \mathbf{u} - \nabla^2 \mathbf{u}] \, dx \, dy \right\rangle \quad (2.9)$$

which is an identity for *any* $\lambda \in [0, 1]$. We now generate volume integrals from this expression which can be related to the long-time-averaged energy dissipation rate per unit mass (in units of ν^3/h^4)

$$\varepsilon := \left\langle \frac{1}{A} \iiint |\nabla \mathbf{u}|^2 \, dV \right\rangle := \left\langle \frac{1}{A} \int_0^{L_x} \int_0^{L_y} \int_{z=f(x, y)}^{z=g(x, y)} |\nabla \mathbf{u}|^2 \, dz \, dy \, dx \right\rangle. \quad (2.10)$$

To do this, (2.9) is integrated over $\lambda \in [0, \Lambda]$ to give

$$\Lambda Gr = \left\langle \frac{1}{A} \int_0^\Lambda \iint_{\mathcal{A}} (\hat{\mathbf{x}} + F_x \hat{\mathbf{z}}) \cdot [\mathbf{u} \cdot \nabla \mathbf{u} - \nabla^2 \mathbf{u}] dx dy d\lambda \right\rangle. \quad (2.11)$$

This can be converted into a volume integral by converting the integral over λ to one over z with the addition of a (Jacobian) scaling factor $\partial z / \partial \lambda|_{x,y} = F_\lambda(x, y, \lambda)$:

$$\Lambda Gr = \left\langle \frac{1}{A} \iiint_{\mathcal{V}(\Lambda)} \mathbf{a} \cdot [\mathbf{u} \cdot \nabla \mathbf{u} - \nabla^2 \mathbf{u}] dx dy dz \right\rangle \quad \forall \Lambda \in [0, 1] \quad (2.12)$$

where

$$\mathbf{a} := \frac{\hat{\mathbf{x}} + F_x \hat{\mathbf{z}}}{F_\lambda} = \frac{\hat{\mathbf{x}} + (z - f) [\ln(g - f)]_x \hat{\mathbf{z}}}{(g - f)} \quad (2.13)$$

eliminating λ in favour of z (recall $g = g(x, y)$ and $f = f(x, y)$). The key now is to lift spatial derivatives off \mathbf{u} and onto \mathbf{a} by judicious use of the divergence theorem. This leads to

$$\begin{aligned} \Lambda Gr = \frac{1}{A} \left\langle \oint_{\partial \mathcal{V}(\Lambda)} (\mathbf{a} \cdot \mathbf{u}) \mathbf{u} \cdot \hat{\mathbf{n}} + \mathbf{u} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{a} - \mathbf{a} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{u} dS \right. \\ \left. - \iiint_{\mathcal{V}(\Lambda)} \mathbf{u} \cdot (\mathbf{u} \cdot \nabla) \mathbf{a} + \mathbf{u} \cdot \nabla^2 \mathbf{a} dV \right\rangle \quad \forall \Lambda \in [0, 1] \end{aligned} \quad (2.14)$$

(note the last term requires the roughness functions f and g to be at least C^3). Due to periodicity over $(x, y) \in [0, L_x] \times [0, L_y]$, the only parts of $\partial \mathcal{V}(\Lambda)$ which need be considered are the lower boundary $\mathcal{S}(0)$ where $\mathbf{u} = \mathbf{0}$ and the interior surface $\mathcal{S}(\Lambda)$. Hence, in fact

$$\begin{aligned} \Lambda Gr = \frac{1}{A} \left\langle \int_{\mathcal{S}(\Lambda)} (\mathbf{a} \cdot \mathbf{u}) \mathbf{u} \cdot \hat{\mathbf{n}} + \mathbf{u} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{a} - \mathbf{a} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{u} dS \right. \\ \left. - \int_{\mathcal{S}(0)} \mathbf{a} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{u} dS \right. \\ \left. - \iiint_{\mathcal{V}(\Lambda)} \mathbf{u} \cdot (\mathbf{u} \cdot \nabla) \mathbf{a} + \mathbf{u} \cdot \nabla^2 \mathbf{a} dV \right\rangle \quad \forall \Lambda \in [0, 1]. \end{aligned} \quad (2.15)$$

Now the strategy is to separately average (2.15) over $\Lambda \in [0, \ell]$ and over $\Lambda \in [1 - \ell, 1]$ and then compute the difference in order to eliminate the Λ -independent $\mathcal{S}(0)$ boundary term. Subtracting $1/\ell \int_0^\ell (2.15) d\Lambda$ from $1/\ell \int_{1-\ell}^1 (2.15) d\Lambda$ gives

$$\begin{aligned} (1 - \ell) Gr = \frac{1}{A} \left\langle \frac{1}{\ell} \int_{1-\ell}^1 \int_{\mathcal{S}(\Lambda)} (\mathbf{a} \cdot \mathbf{u}) \mathbf{u} \cdot \hat{\mathbf{n}} + \mathbf{u} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{a} - \mathbf{a} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{u} dS d\Lambda \right. \\ \left. - \frac{1}{\ell} \int_0^\ell \int_{\mathcal{S}(\Lambda)} (\mathbf{a} \cdot \mathbf{u}) \mathbf{u} \cdot \hat{\mathbf{n}} + \mathbf{u} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{a} - \mathbf{a} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{u} dS d\Lambda \right. \\ \left. - \frac{1}{\ell} \int_{1-\ell}^1 \iiint_{\mathcal{V}(\Lambda)} \mathbf{u} \cdot (\mathbf{u} \cdot \nabla) \mathbf{a} + \mathbf{u} \cdot \nabla^2 \mathbf{a} dV d\Lambda \right. \\ \left. + \frac{1}{\ell} \int_0^\ell \iiint_{\mathcal{V}(\Lambda)} \mathbf{u} \cdot (\mathbf{u} \cdot \nabla) \mathbf{a} + \mathbf{u} \cdot \nabla^2 \mathbf{a} dV d\Lambda \right\rangle \end{aligned} \quad (2.16)$$

This is the generalisation of Seis's (2015) expression (4.10) which can be recovered by setting $\mathbf{a} = \hat{\mathbf{x}}$, taking $\mathcal{S}(\Lambda)$ as the horizontal plane $z = \Lambda$ over $[0, L_x] \times [0, L_y]$ and $\hat{\mathbf{n}} = \hat{\mathbf{z}}$. Notably, there are new integrated volume terms because the linear momentum directed along $\mathcal{C}(\lambda, y)$ is not conserved but these turn out to be subdominant in what follows. From

here, the exercise is to bound the rhs of (2.16) in terms of the energy dissipation rate ε and then to optimise over $\ell \in [0, \frac{1}{2}]$ to produce the best bound on Gr as in Seis (2015). Since our focus is on establishing the scaling exponent of how Gr scales with ε rather than the secondary issue of producing the best estimate for the numerical prefactor, we proceed by employing straightforward conservative estimates. This has the advantage of securing our key result quickly and relatively clearly but more careful estimates could lower the (numerical) bound on Gr but *not*, we contend, the scaling exponent. Firstly,

$$\begin{aligned}
Gr \leq \frac{1}{A\ell(1-\ell)} & \left\{ \langle \int_{1-\ell}^1 \int_{S(\Lambda)} |\mathbf{a} \cdot \mathbf{u}| |\mathbf{u} \cdot \hat{\mathbf{n}}| dS d\Lambda \rangle + \langle \int_{1-\ell}^1 \int_{S(\Lambda)} |\mathbf{u} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{a}| dS d\Lambda \rangle \right. \\
& + \langle \int_{1-\ell}^1 \int_{S(\Lambda)} |\mathbf{a} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{u}| dS d\Lambda \rangle + \langle \int_0^\ell \int_{S(\Lambda)} |\mathbf{a} \cdot \mathbf{u}| |\mathbf{u} \cdot \hat{\mathbf{n}}| dS d\Lambda \rangle^{(1)} \\
& + \langle \int_0^\ell \int_{S(\Lambda)} |\mathbf{u} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{a}| dS d\Lambda \rangle^{(2)} + \langle \int_0^\ell \int_{S(\Lambda)} |\mathbf{a} \cdot (\hat{\mathbf{n}} \cdot \nabla) \mathbf{u}| dS d\Lambda \rangle^{(3)} \\
& + \langle \int_{1-\ell}^1 \iiint_{V(\Lambda)} |\mathbf{u} \cdot (\mathbf{u} \cdot \nabla) \mathbf{a}| dV d\Lambda \rangle + \langle \int_{1-\ell}^1 \iiint_{V(\Lambda)} |\mathbf{u} \cdot \nabla^2 \mathbf{a}| dV d\Lambda \rangle \\
& + \langle \int_0^\ell \iiint_{V(\Lambda)} |\mathbf{u} \cdot (\mathbf{u} \cdot \nabla) \mathbf{a}| dV d\Lambda \rangle^{(4)} + \langle \int_0^\ell \iiint_{V(\Lambda)} |\mathbf{u} \cdot \nabla^2 \mathbf{a}| dV d\Lambda \rangle^{(5)} \Big\} \\
\end{aligned} \tag{2.17}$$

(the red superscripts are just labels). Each of the integrals in (2.17) need to be bounded by a function of ε . We focus on integrals concentrated at the lower boundary and treat first the integral, I_1 , labelled ⁽¹⁾ in (2.17). Firstly converting the surface integral into one over \mathcal{A}

$$I_1 \leq \langle \int_0^\ell \iint_{\mathcal{A}} |\mathbf{a}| \sqrt{1 + F_x^2 + F_y^2} |\mathbf{u}|^2 dx dy d\Lambda \rangle. \tag{2.18}$$

Then using the Fundamental Theorem of Calculus since $\mathbf{u}(x, y, f(x, y)) = \mathbf{0}$ (i.e. on $\mathcal{S}(0)$) and Cauchy-Schwarz gives

$$\begin{aligned}
I_1 & \leq \langle \int_0^\ell \iint_{\mathcal{A}} |\mathbf{a}| \sqrt{1 + F_x^2 + F_y^2} \left| \int_{f(x,y)}^z \frac{\partial \mathbf{u}}{\partial \bar{z}} d\bar{z} \right|^2 dx dy d\Lambda \rangle \\
& \leq \langle \int_0^\ell \iint_{\mathcal{A}} |\mathbf{a}| \sqrt{1 + F_x^2 + F_y^2} \left(\int_{f(x,y)}^z 1^2 d\bar{z} \int_{f(x,y)}^z \left| \frac{\partial \mathbf{u}}{\partial \bar{z}} \right|^2 d\bar{z} \right) dx dy d\Lambda \rangle \\
& \leq \langle \int_0^\ell \iint_{\mathcal{A}} |\mathbf{a}| \sqrt{1 + F_x^2 + F_y^2} \Lambda F_\lambda \int_{f(x,y)}^z \left| \frac{\partial \mathbf{u}}{\partial \bar{z}} \right|^2 d\bar{z} dx dy d\Lambda \rangle \\
& \leq \max_{x,y,\lambda \in \mathcal{V}(\ell)} \left\{ |\mathbf{a}| F_\lambda \sqrt{1 + F_x^2 + F_y^2} \right\} \int_0^\ell \Lambda d\Lambda \langle \iiint |\nabla \mathbf{u}|^2 dV \rangle \\
& \leq \max_{x,y,\lambda \in \mathcal{V}(\ell)} \left\{ \sqrt{1 + F_x^2} \sqrt{1 + F_x^2 + F_y^2} \right\} \times \frac{1}{2} \ell^2 A \varepsilon.
\end{aligned} \tag{2.19}$$

Integral I_4 (labelled ⁽⁴⁾ in (2.17)) is treated similarly albeit with an extra integration in

Λ giving rise to ℓ^3 in the estimate:

$$\begin{aligned}
I_4 &\leq \langle \int_0^\ell \iiint_{\mathcal{V}(\Lambda)} |\nabla \mathbf{a}| |\mathbf{u}|^2 dV d\Lambda \rangle \leq \langle \int_0^\ell \int_0^\Lambda \iint_{\mathcal{A}} F_\lambda |\nabla \mathbf{a}| |\mathbf{u}|^2 dx dy d\lambda d\Lambda \rangle \\
&\leq \max_{x,y,\lambda \in \mathcal{V}(\ell)} \left\{ F_\lambda^2 |\nabla \mathbf{a}| \right\} \int_0^\ell \int_0^\Lambda \lambda d\lambda d\Lambda \langle \iiint_{\mathcal{V}(\ell)} |\nabla \mathbf{u}|^2 dV \rangle \\
&\leq \max_{x,y,\lambda \in \mathcal{V}(\ell)} \left\{ F_\lambda^2 |\nabla \mathbf{a}| \right\} \times \frac{1}{6} \ell^3 A \varepsilon
\end{aligned} \tag{2.20}$$

The remaining integrals, I_2 , I_3 and I_5 , are treated as follows:

$$\begin{aligned}
I_2 &\leq \langle \iint_{\mathcal{A}} \int_{f(x,y)}^{F(x,y,\ell)} \frac{|\hat{\mathbf{n}} \cdot \nabla \mathbf{a}| \sqrt{1 + F_x^2 + F_y^2}}{F_\lambda} |\mathbf{u}| dx dy dz \rangle \\
&\leq \left[\frac{1}{A} \iiint_{\mathcal{V}(\ell)} \frac{|\hat{\mathbf{n}} \cdot \nabla \mathbf{a}|^2 (1 + F_x^2 + F_y^2)}{F_\lambda^2} dV \right]^{\frac{1}{2}} \left[\langle \iiint_{\mathcal{V}(\ell)} |\mathbf{u}|^2 dV \rangle \right]^{\frac{1}{2}} \\
&\leq \left[\iiint_{\mathcal{V}(\ell)} \frac{|\hat{\mathbf{n}} \cdot \nabla \mathbf{a}|^2 (1 + F_x^2 + F_y^2)}{F_\lambda^2} dV \right]^{\frac{1}{2}} \times \left[\max_{(x,y) \in \mathcal{A}} F_\lambda^2 \right]^{\frac{1}{2}} \times A \sqrt{\frac{1}{2} \ell^2 \varepsilon} \\
&\leq \left[\iint_{\mathcal{A}} \max_{\Lambda \in [0,\ell]} \frac{|\hat{\mathbf{n}} \cdot \nabla \mathbf{a}|^2 (1 + F_x^2 + F_y^2)}{F_\lambda} dx dy \right]^{\frac{1}{2}} \times \left[\max_{(x,y) \in \mathcal{A}} F_\lambda^2 \right]^{\frac{1}{2}} \times A \sqrt{\frac{1}{2} \ell^3 \varepsilon}
\end{aligned} \tag{2.21}$$

where $\hat{\mathbf{n}} = (-F_x \hat{\mathbf{x}} - F_y \hat{\mathbf{y}} + \hat{\mathbf{z}}) / \sqrt{1 + F_x^2 + F_y^2}$ and the last line follows using the same type of estimates as in (2.19) and noting that $F_\lambda = g(x, y) - f(x, y)$ is independent of λ and strictly positive. Respectively

$$\begin{aligned}
I_3 &\leq \langle \iint_{\mathcal{A}} \int_{f(x,y)}^{F(x,y,\ell)} \frac{|\mathbf{a}| \sqrt{1 + F_x^2 + F_y^2}}{F_\lambda} |\nabla \mathbf{u}| dx dy dz \rangle \\
&\leq \left[\iiint_{\mathcal{V}(\ell)} \frac{|\mathbf{a}|^2 (1 + F_x^2 + F_y^2)}{F_\lambda^2} dV \right]^{\frac{1}{2}} \times \sqrt{A \varepsilon} \\
&\leq \left[\iint_{\mathcal{A}} \int_0^\ell \frac{(1 + F_x^2)(1 + F_x^2 + F_y^2)}{F_\lambda^3} d\lambda dx dy \right]^{\frac{1}{2}} \times \sqrt{A \varepsilon} \\
&\leq \left[\frac{1}{A} \iint_{\mathcal{A}} \max_{\Lambda \in [0,\ell]} \left\{ (1 + F_x^2)(1 + F_x^2 + F_y^2) \right\} \frac{dx dy}{F_\lambda^3} \right]^{\frac{1}{2}} \times A \sqrt{\ell \varepsilon}
\end{aligned} \tag{2.22}$$

and

$$\begin{aligned}
I_5 &\leq \int_0^\ell \left[\iiint_{\mathcal{V}(\ell)} |\nabla^2 \mathbf{a}|^2 dV \right]^{\frac{1}{2}} \left[\langle \iiint_{\mathcal{V}(\ell)} |\mathbf{u}|^2 dV \rangle \right]^{\frac{1}{2}} d\Lambda \\
&\leq \left[\frac{1}{A} \iiint_{\mathcal{V}(\ell)} |\nabla^2 \mathbf{a}|^2 dV \right]^{\frac{1}{2}} \times \left[\max_{(x,y) \in \mathcal{A}} F_\lambda^2 \right]^{\frac{1}{2}} \times \ell^2 A \sqrt{\frac{1}{2} \varepsilon} \\
&\leq \left[\frac{1}{A} \iint_{\mathcal{A}} F_\lambda \max_{\Lambda \in [0,\ell]} |\nabla^2 \mathbf{a}|^2 dx dy \right]^{\frac{1}{2}} \times \left[\max_{(x,y) \in \mathcal{A}} F_\lambda^2 \right]^{\frac{1}{2}} \times A \sqrt{\frac{1}{2} \ell^5 \varepsilon}.
\end{aligned} \tag{2.23}$$

The estimates for the corresponding integrals centred at the top boundary are exactly

analogous, and grouping the contributions together for each term, we get a simplified ‘inequality’ version of (2.16)

$$Gr \leq \frac{1}{\ell(1-\ell)} \left\{ (B_1\ell^2 + B_4\ell^3)\varepsilon + (B_2\ell + B_3 + B_5\ell^2)\sqrt{\ell\varepsilon} \right\}. \quad (2.24)$$

where the coefficients B_i represent the $O(1)$ numerical factors (in the sense of $Gr \rightarrow \infty$) of the i th integral bound when a factor of A is factored out and the dominant ℓ and ε behaviour (which both are not $O(1)$) is separated off. The idea now is to minimise the rhs over the choice of $\ell \in (0, \frac{1}{2})$ in the turbulent limit $Gr \rightarrow \infty$. Here, $\varepsilon \rightarrow \infty$ (naive scalings suggest $Gr \lesssim \varepsilon \lesssim Gr^2$) and the optimal $\ell \rightarrow 0$ so, working to leading order,

$$Gr \leq B_1\ell\varepsilon + B_3\sqrt{\varepsilon/\ell} + \text{h.o.t.} \quad (2.25)$$

and now it is clear that all the new integral contributions due to the roughness are subdominant. Instead the roughness manifests itself as adjusted numerical coefficients for the integrals which arise in the smooth situation (Seis 2015). The minimising ℓ is $(B_3/2B_1)^{2/3}\varepsilon^{-1/3}$ and

$$Gr \leq \frac{3}{2}(2B_1B_3^2)^{1/3} \times \varepsilon^{2/3} \quad \text{or} \quad \frac{2\sqrt{3}}{9B_3\sqrt{B_1}} \times Gr^{3/2} \leq \varepsilon \quad (2.26)$$

where

$$B_1 = \sum_{\lambda=0}^1 \max_{(x,y) \in \mathcal{A}} \left\{ \frac{1}{2} \sqrt{1 + F_x^2} \sqrt{1 + F_x^2 + F_y^2} \right\}, \quad (2.27)$$

$$B_3 = \sum_{\lambda=0}^1 \left[\frac{1}{A} \iint_{\mathcal{A}} \frac{(1 + F_x^2)(1 + F_x^2 + F_y^2)}{[g(x, y) - f(x, y)]^3} dx dy \right]^{\frac{1}{2}}. \quad (2.28)$$

The lower bound in (2.26) indicates that turbulence *decreases* dissipation for a given applied pressure gradient as per the smooth wall case (Constantin & Doering 1995; Seis 2015). However, as there, rewriting the result in terms of the *a priori* unknown mean flow recovers the familiar upper bound situation. Taking $\langle \iiint \mathbf{u} \cdot (2.1) dV \rangle$ connects the mean flow U with the applied pressure gradient and ensuing dissipation rate,

$$U := \left\langle \frac{1}{A} \iiint \mathbf{u} \cdot \hat{\mathbf{x}} dV \right\rangle = \varepsilon / Gr. \quad (2.29)$$

This can be used to eliminate the pressure gradient (Gr) to get

$$\varepsilon \leq \frac{27}{4} B_1 B_3^2 U^3 \quad \text{or} \quad \varepsilon \leq \frac{27}{4} B_1 B_3^2 \quad (\text{in units of } U^3/h) \quad (2.30)$$

so that the bound predicts that the energy dissipation rate becomes independent of the viscosity as the viscosity goes to zero - Kolmogorov scaling - just as in the smooth wall calculation (Constantin & Doering 1995, Seis 2015, and Plasting & Kerswell 2005 for pipe flow).

3. Oscillatory flow across topography: the tidal problem

As a simple application of the above result, we now consider the ocean tidal problem of oscillatory flow across bottom topography (and a free top surface). This situation is modelled by assuming an oscillatory pressure gradient driving the flow directly i.e. $\mathcal{G} \sim \omega^* U^*$ where the tidal frequency $\omega^* = 2\pi/12 \text{ hours} = 1.4 \times 10^{-4} \text{ s}^{-1}$ and $U^* \approx$

0.1ms^{-1} . We consider a symmetrised problem where the top boundary is defined by $g(x, y) = 1 - f(x, y)$ so that the real free surface position on average is the (symmetric) midplane of the extended domain and $\frac{1}{2}h$ is then the mean ocean depth. By symmetry, the maximum dissipation in the extended domain is exactly double the maximum dissipation in the ‘ocean’ domain. Further restricting the flow in the extended domain to have zero vertical motion and zero stress across $z = \frac{1}{2}$ (the horizontal free surface approximation) can only reduce the maximum dissipation possible (by restricting the competitor space) so halving the dissipation bound from the unrestricted, extended domain should be an upper bound on the dissipation in a flat surface ocean ($z \leq \frac{1}{2}$).

Taking a typical ocean depth $\frac{1}{2}h = 1000\text{m}$, the Grashof number $Gr = 1.12 \times 10^{17} \gg 1$ and the non-dimensionalised tidal frequency

$$1 \ll \omega := \frac{h^2 \omega^*}{\nu} = \sqrt{\frac{h\mathcal{G}}{U^2}} \sqrt{Gr} \ll Gr \quad (3.1)$$

where $\Upsilon := h\mathcal{G}/U^2$ is a second non-dimensional number independent of ν which is here $O(1)$. This makes it clear that in the limit $\nu \rightarrow 0$ (with everything else kept fixed), $Gr \rightarrow \infty$ with $\omega \sim \sqrt{Gr}$. The governing equation for the problem is then

$$\frac{\partial \mathbf{u}}{\partial t} + 2\boldsymbol{\Omega} \times \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u} + \nabla p - \nabla^2 \mathbf{u} = Gr \Gamma(t) \hat{\mathbf{x}}, \quad (3.2)$$

the flow is assumed incompressible and a planetary rotation $\boldsymbol{\Omega}$ is also included for completeness ($|\boldsymbol{\Omega}| = \frac{1}{2}\omega$). The oscillatory function $\Gamma(t)$ is defined such that

$$\max_{t \in [0, 2\pi/\omega]} |\Gamma(t)| = 1 \quad (3.3)$$

but is otherwise left unspecified for clarity. As before, the analysis starts by taking the line integral of (3.2) along $\mathcal{C}(\lambda, y)$ and integrating over y as above in §2 but now also multiplying by $\Gamma(t)$ to rectify the forcing pressure gradient. This leads to an extended version of (2.8)

$$\begin{aligned} A Gr \Gamma(t)^2 &= \Gamma(t) \frac{\partial}{\partial t} \iint_{\mathcal{A}} (\hat{\mathbf{x}} + F_x \hat{\mathbf{z}}) \cdot \mathbf{u} \, dx \, dy \\ &\quad + \Gamma(t) \iint_{\mathcal{A}} (\hat{\mathbf{x}} + F_x \hat{\mathbf{z}}) \cdot [2\boldsymbol{\Omega} \times \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u} - \nabla^2 \mathbf{u}] \, dx \, dy \end{aligned} \quad (3.4)$$

Now long time averaging leads to

$$\begin{aligned} A Gr \langle \Gamma(t)^2 \rangle &= - \langle \Gamma_t \iint_{\mathcal{A}} (\hat{\mathbf{x}} + F_x \hat{\mathbf{z}}) \cdot \mathbf{u} \, dx \, dy \rangle \\ &\quad + \langle \Gamma(t) \iint_{\mathcal{A}} (\hat{\mathbf{x}} + F_x \hat{\mathbf{z}}) \cdot [2\boldsymbol{\Omega} \times \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u} - \nabla^2 \mathbf{u}] \, dx \, dy \rangle \end{aligned} \quad (3.5)$$

where integration by parts in time has been used to transfer the time derivative onto Γ . Integrating over $\lambda \in [0, \Lambda]$ and converting to a volume integral over $\mathcal{V}(\Lambda)$, gives

$$\Lambda Gr \langle \Gamma(t)^2 \rangle = \frac{1}{A} \langle \iiint_{\mathcal{V}(\Lambda)} \Gamma(t) \mathbf{a} \cdot [\mathbf{u} \cdot \nabla \mathbf{u} - \nabla^2 \mathbf{u}] + [\Gamma \mathbf{a} \times 2\boldsymbol{\Omega} - \Gamma_t \mathbf{a}] \cdot \mathbf{u} \, dx \, dy \, dz \rangle \quad (3.6)$$

for all $\Lambda \in [0, 1]$. The first term on the rhs is as before albeit with an extra factor of $\Gamma(t)$. Since this is bounded in modulus by 1, the subsequent estimates are unchanged. The new second term on the rhs is of the form of I_5 and can be similarly estimated as

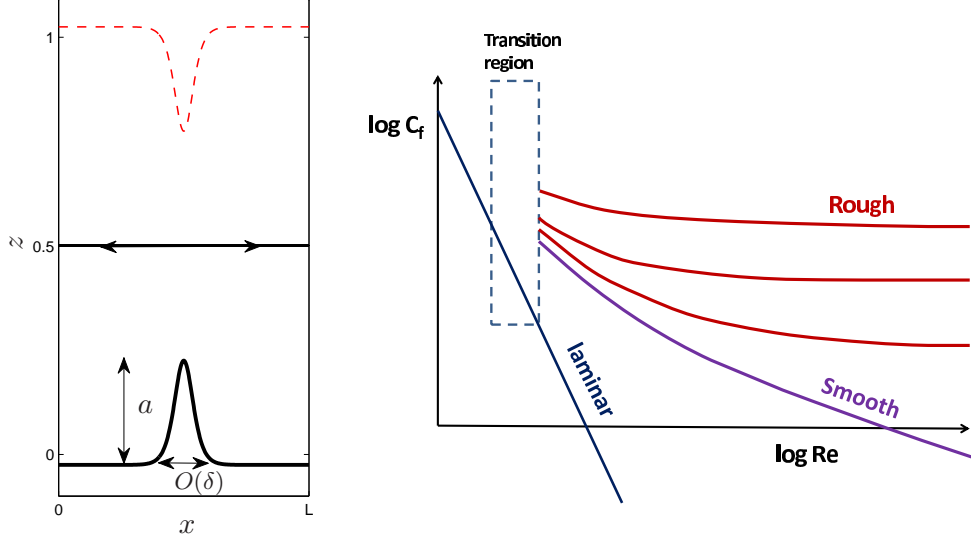

FIGURE 2. Left: the 2D ridge tidal problem with the ocean represented by the region $z \leq \frac{1}{2}$. Right: a cartoon of the Moody diagram for pipe flow (Moody 1944): $C_f := \varepsilon/(U^3/h)$, laminar flow has $C_f \sim 1/Re$, turbulent smooth pipe data suggests $C_f \sim 1/(\log Re)^2$ at least to $Re = O(10^8)$ and turbulent rough pipe data has $C_f \sim O(1)$ as $Re \rightarrow \infty$. Three lines are shown for rough pipe flow with the data increasing to higher C_f as the representative height of the roughness increases.

adding a new term

$$\left[\frac{1}{A} \iint_{\mathcal{A}} F_{\lambda} \max_{\Lambda \in [0, \ell]} |\Gamma \mathbf{a} \times 2\mathbf{\Omega} - \Gamma_t \mathbf{a}|^2 dx dy \right]^{\frac{1}{2}} \times \left[\max_{(x, y) \in \mathcal{A}} F_{\lambda}^2 \right]^{\frac{1}{2}} \times A \sqrt{\frac{1}{2} \ell^5 \varepsilon} \quad (3.7)$$

to (2.24). Since both $\mathbf{\Omega}$ and $\Gamma_t = O(\omega \Gamma)$ are $O(\sqrt{Gr})$, the leading order version of (2.24) is potentially modified to

$$Gr \leq B_1 \ell \varepsilon + (B_3 + B_5 \ell^2 \sqrt{Gr}) \sqrt{\varepsilon/\ell} + \text{h.o.t.} \quad (3.8)$$

The minimiser, however, remains $\ell \sim \varepsilon^{-1/3}$ with the new term $O(Gr^{-1/2})$ smaller than the other two terms. Hence the rotation and oscillation are *not* important at leading order in the bound on the energy dissipation rate for tidal flow over topography.

3.1. A simple example

Here we consider a 2D ridge of height $a < \frac{1}{2}$ and horizontal extent $a\delta$

$$f(x) := a \operatorname{sech}^2\left(\frac{x - \frac{1}{2}L}{a\delta}\right) - \frac{2a^2\delta}{L} \tanh\left(\frac{L}{2a\delta}\right) \quad (3.9)$$

over $x \in [0, L]$ (the second term on the rhs ensures the roughness has zero mean over x): see figure 2. This roughness function is not periodic over $[0, L]$ but in the steep ($\delta \ll 1$) isolated ($a\delta \ll L$) ridge limit this can be ignored. In this limit, it is straightforward to approximate B_1 and B_3 as follows

$$B_1 = \max_{x \in [0, L]} (1 + f_x^2) \approx \frac{16}{27\delta^2}, \quad B_3 = 2 \left[\frac{1}{L} \int \frac{(1 + f_x^2)^2}{(1 - 2f)^3} dx \right]^{\frac{1}{2}} \approx \frac{2}{\sqrt{2L(1 - 2a)^3 \delta^3}},$$

so the dissipation rate per unit mass is

$$\varepsilon \leq \frac{4U^3}{L(1-2a)^3\delta^5} \quad (\text{in units of } \nu^3/h^4) \quad (3.10)$$

(including the $\frac{1}{2}$ to reflect the fact that the ocean is strictly in $z \leq \frac{1}{2}$). This can be re-expressed using inertial units to give the familiar bound independent of the viscosity

$$\varepsilon \leq \frac{4}{L(1-2a)^3\delta^5} \quad (\text{in units of } U^3/h). \quad (3.11)$$

Since this is the leading term due to the ridge (the dissipation bound for zero topography is $O(\delta^5)$ smaller), this expression can be viewed as giving the enhanced dissipation caused by the ridge per unit length of the domain $[0, L]$.

4. Discussion

Using a new bounding technique (Otto & Seis 2011; Seis 2015), this paper has derived an upper bound on the energy dissipation rate (per unit mass) ε for pressure-driven flow through a rough channel with bottom $z = f(x, y)$ and top $z = g(x, y)$ (f and g at least C^3) such that the average height is h in the limit of vanishing viscosity of the form

$$\varepsilon \leq cU^3/h$$

where U is the mean flow through the channel and

$$c := \frac{27}{8} \sum_{\lambda=0}^1 \max_{(x,y) \in \mathcal{A}} \left\{ \sqrt{1+F_x^2} \sqrt{1+F_x^2+F_y^2} \right\} \\ \times \left(\sum_{\lambda=0}^1 \left[\frac{1}{A} \iint_{\mathcal{A}} \frac{(1+F_x^2)(1+F_x^2+F_y^2)}{[g(x,y)-f(x,y)]^3} dx dy \right]^{\frac{1}{2}} \right)^2$$

with $F(x, y, \lambda) := (1-\lambda)f(x, y) + \lambda g(x, y)$ and $\mathcal{A} := [0, L_x] \times [0, L_y]$. The fact that bound predicts that the dissipation rate approaches a finite limit (in inertial units) as the viscosity vanishes - so-called Kolmogorov scaling - then captures the observed scaling of turbulent data in rough pipes - see figure 2 for a cartoon of the classic Moody diagram (Moody 1944) - and indicates that the well-known discrepancy between the bound and data scalings in the smooth wall case (Constantin & Doering (1995); Plasting & Kerswell (2005); Seis (2015) and figure 2) is an exception rather than the rule. Interestingly, boundary crossflow produced by suction instead of roughness also seems to achieve the same effect in plane Couette flow: bounds and data have the same Kolmogorov scaling for non-zero suction but disagree for zero suction (Doering et al. 2000). These observations, which may also extend to convection although the available data is so far only suggestive (see Goluskin & Doering (2016)), substantially enhance the credentials of the bounding approach as a viable way to extract key scaling laws in real turbulent flows where smooth walls are not generic.

There is, of course, room for improvement. The bound derived here requires C^3 differentiability of the roughness whereas it would be better (and more realistic) to only require continuous, piecewise differentiability. This would allow sharp corners such as those present in roughness created by sand granules to be treated. It is possible that better functional analytic estimates may achieve this as well as reducing the numerical prefactor c (e.g. by replacing the infinity norm present by a less extreme norm). However, it seems difficult to see how the exponent in the scaling law (i.e. $\varepsilon \sim Re^0 U^3/h$ as $Re \rightarrow \infty$) could

be changed. From a mathematical perspective, formulating the full variational equations underlying the Otto-Seis ‘boundary layer’ method presents an enticing challenge with the potential for revealing valuable insights into this new method. It was, after all, only after the full variational equations were identified for the Doering-Constantin background method that an intimate connection was made to the Malkus-Howard-Busse bounding approach (Kerswell 1997, 1998).

A significant challenge for the bounding approach remains, however, deriving a dissipation bound on shearing systems with rough boundaries (e.g. rough plane Couette flow). Here, unlike pressure-driven flow through a *stationary* rough channel, one rough boundary moving relative to another means that there has to be motion locally perpendicular to one boundary and therefore work done by the pressure enters the calculation. So far all bounding approaches eliminate the pressure as soon as possible so a totally different approach will be needed. Nevertheless it is reasonable to suppose that a dissipation bound will be derived with Kolmogorov scaling which is what is observed in rough-walled Taylor-Couette flow. If one or both of the walls are smooth, however, the observed dissipation rate then drops off like $\sim 1/(\log Re)^2$ mimicking the situation in pipe flow (Cadot et al. 1997; van den Berg et al. 2003).

Finally, an application of the new bound has been made to a problem of interest in ocean modelling. This warrants further development to include stable stratification and a refocus on the turbulent mixing that can be caused by isolated topography (typically by internal wave breaking) as this is an important yet poorly-known input in ocean models (e.g. see Melet et al. 2016 and references therein).
